Keywords: Cellulose nanofibrils; nanocellulose films; piezoelectric sensor materials; image-based analysis; relative permittivity; sensitivity measurement.

Abstract

Self-standing films (45- μm thick) of native cellulose nanofibrils (CNF) were synthesized and characterized for their piezoelectric response. The surface and the microstructure of the films were evaluated with image-based analysis and scanning electron microscopy (SEM). The measured dielectric properties of the films at 1 kHz and 9.97 GHz indicated a relative permittivity of 3.47 and 3.38 and loss tangent $\tan \delta$ of 0.011 and 0.071, respectively. The films were used as functional sensing layers in piezoelectric sensors with corresponding sensitivities of 4.7 to 6.4 pC/N in ambient conditions. This piezoelectric response is expected to increase remarkably upon film polarization resulting from the alignment of the cellulose crystalline regions in the film. The CNF sensor characteristics were compared with those of polyvinylidene fluoride (PVDF) as reference piezoelectric polymer. Overall, the results suggest that CNF is a suitable precursor material for disposable piezoelectric sensors, actuator or energy generators with potential applications in the fields of electronics, sensors and biomedical diagnostics.

1. Introduction

Cellulosic nanofibrils and nanocrystals¹, referred to as nanocelluloses, are interesting renewable bio-based nanomaterials with potential applications in different fields. The nanoscale dimensions and strong ability to form entangled porous networks make nanocelluloses suitable

materials for fabrication of light-weight membranes, films, and nanopapers, all of which can be processed in aqueous media. Processing in aqueous media ensures low cost and high throughput manufacturing of functional devices for electronics^{2,3}, sensing⁴ and optics⁵. Furthermore, the combination of nanocelluloses with water-processable carbon-based nanomaterials, such as carbon nanotubes or graphene, is beneficial towards flexible and disposable devices, including supercapacitors⁶⁻⁸ among many others.

The piezoelectricity of wood, i.e., the change of electrical polarization in a material in response to mechanical stress⁹, has been known for decades^{10,11}. The piezoelectric effect is highly enhanced if one considers the isolated crystalline building blocks of wood, namely cellulose nanocrystals (CNC)^{12,13}. However, related issues has been covered in the scientific literature to a very limited extent and only few recent reports discuss experimental evidence of CNC piezoelectricity^{12,14}. Notably, the higher aspect-ratio cellulose nanofibrils (CNF), containing both crystalline (cellulose I¹) and less ordered domains of cellulose, may offer versatile options as far as the synthesis of self-standing films and nanopapers is profitable. Moreover, despite the expected random alignment of crystalline regions in CNF, their films may still be piezoelectric due to the film fabrication process driven alignment. To our knowledge, piezoelectric measurements of CNF films have not been attempted before us^{15,16}.

In this study, CNF films were fabricated and their physical, dielectric and electromechanical behavior was characterized. The microstructure of the films was studied using scanning electron microscopy (SEM). Also, the surface of the films was evaluated through measurements based on

optical imaging. The films were used as functional materials in piezoelectric sensors and their sensitivity was measured by using a custom-built setup. The sensors were excited with a mechanical shaker that delivered a sinusoidal force input and the charge generated by the sensor was measured. The sensitivity is defined here as the charge generated by the sensor divided by the force applied to excite the sensor. Finally, the nonlinearity and hysteresis of the piezoelectric sensors were measured and compared with those of polyvinylidene fluoride (PVDF) which was used as a reference piezoelectric polymer.

2. Materials and methods

2.1 Nanocellulose Piezoelectricity

The compression of a piezoelectric film by an external force causes charge separation in the film generating a noticeable voltage between two electrodes. The piezoelectric coefficient d_{mn} is related to the charge density generated under a certain applied stress. The components of third-rank tensor with piezoelectric coefficients d_{mn} is expressed as a 3×6 matrix, where $m = 1, 2, 3$ refers to the electrical axis and $n = 1, 2, \dots, 6$ to the mechanical axis⁹. The main axes 1, 2 and 3 correspond to length, width and thickness, whereas the shear around these axes is represented by 4, 5 and 6.

The piezoelectric tensor d_{mn} can be derived from the symmetry of a cellulose crystal lattice, formed by unit cells of cellulose molecules $([C_6H_{10}O_5]_n)^{11}$. The cellulose belongs to the monoclinic symmetry with space group of $C_2 \parallel x_3$ having a following piezoelectric tensor:

$$d_{mn} = \begin{pmatrix} 0 & 0 & 0 & d_{14} & d_{15} & 0 \\ 0 & 0 & 0 & d_{24} & d_{25} & 0 \\ d_{31} & d_{32} & d_{33} & 0 & 0 & d_{36} \end{pmatrix}. \quad (1)$$

This tensor is valid for a single cellulose crystal. However, for an assembly of randomly aligned crystals, such as in a film of CNF, the overall piezoelectric response results from the combination of the different coefficients. For example, in the case of wood, arrangement of fibers and accompanied cellulose crystals have been shown to exhibit greatly reduced effective piezoelectric tensor:

$$d_{mn} = \begin{pmatrix} 0 & 0 & 0 & d_{14} & 0 & 0 \\ 0 & 0 & 0 & 0 & d_{25} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \quad (2)$$

where $d_{14} = -d_{25}^{10,11}$.

2.2. CNF film fabrication

Figure 1 describes schematically the deconstruction of nanocellulose from wood cellulose fibers¹. In this work, fibers obtained from birch wood by sulfate digestion and subsequent bleaching were suspended in water and then processed through a Masuko grinder using three consecutive passes and further homogenized using six passes at 2000 bar pressure by using a M110P microfluidizer (Microfluidics Corp., Newton, MA, USA) equipped with two chambers (200 and 100 μm size) in series. The resulting cellulose fibrils can be considered as composed of ordered crystalline (cellulose I¹) and less ordered cellulose domains as well as amorphous residual heteropolysaccharides and lignin, which may be present in very low concentration. Even

at low CNF concentration, it forms a highly viscous aqueous dispersion, a hydrogel¹⁷. Films based on CNF were fabricated by pressure filtering (15-30 min) followed by pressing and drying in a hot-press at 100 °C for 2 h, as has been described previously in detail¹⁸. An example of the resulting self-standing CNF films is presented in Figure 2a.

2.3. CNF film characterization

The CNF films were characterized by Scanning Electron Microscopy (SEM, Zeiss ULTRApplus). Cross-sectional images were obtained by cryo-fracture of the CNF film under liquid nitrogen and by gluing the film to holders containing conductive carbon cement. The samples were coated with a thin carbon layer to provide electrical conductivity prior to SEM imaging. Energy Dispersive X-ray Spectroscopy (EDS, INCA Energy 350 with INCAx-act detector) was used to analyse the purity of the CNF film. The apparent film density was calculated from a 5 cm x 8 cm cut by assuming an even film thickness (as obtained from the SEM analysis) and mass (microbalance).

The surface topography of the CNF film was examined through photometric stereo imaging and subsequent image analysis. Photometric stereo¹⁹ imaging is a widely used technique in computer graphics for surface analysis and reconstruction²⁰, and it has also been successfully applied in small-scale surface topography measurement, e.g., in paper products²¹ and dermatology²². In the photometric stereo setup, the translucent CNF sample was fixed on top of a flat black sheet of cardboard while it was imaged with a camera placed atop. Four images were acquired from the sample with different, but precisely known, illumination directions, using blue

LEDs whose dominant wavelength was 460 nm. The surface orientation (i.e., gradients) at each pixel was estimated from the photographs (see Ref. ¹⁹ for details). The surface topography map was then reconstructed from the gradient fields by integration²³. The photographs were captured using a digital systems camera (Canon EOS 550D) and a magnifying macro lens (Canon MP-E 65 mm). With a slight magnification (1.3:1), a pixel size of 3.27 μm x 3.27 μm on an image area of approximately 17 mm x 11 mm was achieved.

The dielectric properties of the CNF film were evaluated at low frequency (100 Hz to 1 MHz) by using a LCR meter (precision LCR meter 4284A, Keysight Technologies, USA). Frequencies below 100 Hz were left out from the measurement due to low accuracy of the LCR at these frequencies and capacitance values below 100 pF. In order to improve the reliability of the measurement, a stack of two films (45 μm each for a total thickness of 96 μm) was used. The sample was compressed gently between two external electrodes (diameters 25 and 17.5 mm) in a custom-made measurement setup. The holder of the smaller electrode was made from soft rubber, covered with a conductive layer. This enabled the sample to align better between the electrodes and improved the application of small pressures to avoid deformation of the sample. Further, a high frequency analysis was used to confirm the reliability of the LCR measurements; thus, a single layer of the CNF film was characterized at 9.97 GHz using a Split Post Dielectric Resonator (QWED, Warsaw, Poland). This technique enables measurement without electrodes. Prior to both dielectric measurements the films were held at 100 °C and equilibrated for 60 min in order to minimize the effect of air moisture in the results. Ferroelectric tester (Precision LC, Radiant technologies, USA) was used to measure the ferroelectric hysteresis of the CNF film up to 50 V/ μm electric field and 10 Hz frequency.

2.4. CNF and PVDF sensor assembly

Electrode substrates for the CNF sensor assembly were fabricated with polyethylene terephthalate (PET, Melinex ST506) by e-beam evaporation (Varian vacuum evaporator). Electrodes were formed by evaporating 100 nm thick copper (Cu) layer through a laser-cut stencil shadow mask.

The preparation of piezoelectric CNF sensor is described in Figure 2. Before the sensor assembly, the CNF film shown in Figure 2a was cut into round shapes with a diameter slightly larger than that of the electrodes, thus to avoid electrical breakdown over the edges. The structure of the sensors is presented schematically in Figure 2b,c. The CNF sensor was then sandwiched between two electrodes and fixed together from outside of the electrode perimeter using a sticker film (two-way glue, manufactured by Kuretake Co.). A photograph of a fabricated sensor is presented in Figure 2d. The total thickness of the assembled sensor was about 300 μm , as measured with a micrometer gauge.

In total, four CNF sensor elements with an electrode diameter of 15 mm were assembled and characterized. In addition, one larger CNF sensor (with diameter of 20 mm) was assembled and tested to study the sensitivity distribution over the sensor surface. A polyvinylidene fluoride (PVDF) sensor was assembled using the same method as for the CNF sensors and used as a reference. PVDF has been widely used in mechanical (e.g. pressure, acceleration, vibration and tactile sensors etc.), acoustics and IR sensors²⁴, in the application areas including energy

conversion²⁵ and medical measurements^{26–28}. Specifically, an un-metallized, 28 μm thick PVDF film manufactured by Measurement Specialties Inc. (Hampton, USA) was used in this study²⁹.

2.5. Piezoelectric sensitivity measurements

A Brüel & Kjaer Mini-Shaker Type 4810 generating a dynamic excitation force was used in the sensor sensitivity measurements. A sinusoidal input for the shaker was provided with a Tektronix AFG3101 function generator. A commercial high sensitivity dynamic force sensor (PCB Piezotronics, model 209C02) was used as a reference sensor for the dynamic excitation force. A load cell (Measurement Specialties Inc., model ELFS-T3E-20L) was used as reference sensor to measure the static force between the sample and shaker's piston (diameter 4 mm). A pre-compression, which produces the static force, is needed to keep the sample in place and to prevent the piston from jumping off the surface during the measurement. Figure 3a shows the setup used to measure the sensor sensitivity. The same measurement principle has been previously used to evaluate the sensor sensitivity of piezoelectric polymer film (PVDF)^{26–28,30–33}.

The sensor sensitivity is closely related to the longitudinal piezoelectric coefficient d_{33} . The longitudinal d_{33} coefficient describes the electric polarization generated in the same direction as the stress applied³⁴. Thus, in the measurement of the sensor sensitivity, the electrodes were located on the top and the bottom of the tested film, which was excited with a dynamic force in the Z or thickness direction. The sensitivity is defined here as the charge generated by the sensor divided by the normal force used to excite the sensor (C/N units).

To measure the sensor sensitivity of the four CNF sensors (15 mm diameter) in the thickness direction, the sensor was placed horizontally on the metal plate, see Figure 2e. The charge developed by the sensor was measured with a custom-made combination of a charge amplifier and a 16-bit AD-converter. The connection to the AD-converter from the sensor was provided via coaxial wires and crimp connectors (Nicomatic Crimpflex). The AD-converter also had additional channels for sampling the voltage signals from the reference sensors. The measured data was processed to solve the sensitivity of the sensor to the force. Since the excitation force was sinusoidal, the sensitivity was calculated simply by dividing the amplitudes of the respective signals. Possible baseline drift in the signals was removed with high-pass filtering before the sinusoidal amplitudes were solved by fitting sinusoidal waveforms to the signals, as described in the IEEE Standard for Digitizing Waveform Recorders (IEEE Std 1241).

A static force of approximately 3 N was applied. The sensor was excited with dynamic sinusoidal 2 Hz force input signal of 1.4 N (peak-to-peak). The excitation was applied in the middle of the sensor. The measurement was repeated three times; between the measurements the static force was relieved and the sensor was re-positioned on the metal plate for a new measurement. The same measurements were conducted from both sides of the sensor, resulting in a total of six excitation rounds per sensor.

2.6. Measurement of sensor characteristics

In addition to the piezoelectric sensitivity measurements described in the previous Section, more comprehensive measurements were performed on the CNF sensor with the electrode

diameter of 20 mm. Likewise, similar measurements were carried out with the reference PVDF sensor. First, the sensitivity distribution over the sensor surface was measured. The CNF and PVDF sensors were excited by applying force to nine different locations on the sensor area, one at a time (see Figure 3b). The same positions were excited from both sides of the sensor, resulting in a total of 18 excitation rounds per sensor.

Next, the charge developed by the CNF and PVDF sensors was measured as a function of dynamic excitation force to determine the nonlinearity of the sensor. The amplitude of the dynamic excitation force was altered from approximately 0.1 N to 5 N (peak-to-peak) with a frequency of 2 Hz. Finally, the hysteresis error for the sensors was determined. The sensor hysteresis error is defined as the deviation of the sensor's output at a specified point of the input signal when this point is approached from opposite directions³⁵. Here the sensor hysteresis curve was determined by measuring the generated charge as a function of dynamic excitation force, first by increasing the force between the excitation rounds (duration about 10 seconds) and then by decreasing it. At each excitation round, no fatigue in sensor signals was observed during the excitation. The excitation force range was approximately 0.7-2.8 N (peak-to-peak) with a frequency of 2 Hz.

3. Results

3.1. CNF film characterization

Cross-sectional and plane view micrographs (SEM) of a CNF film are shown in Figure 4. The cross-section of the film (Figure 4a) reveals a layered, porous structure with an average thickness of $45 \pm 3 \mu\text{m}$. The film structure is similar to those reported in a previous study¹⁸. The surface view of the film (Figure 4b) shows a random orientation of the nanofibrils. No traces of defects were found. The density of the CNF film was estimated to be 1.38 g/cm^3 , based on measurement of film dimensions and weight measured in ambient air.

The photometric stereo images and the reconstructed surface topography map reveal a prominent streaky structure on the surface of the CNF film. Figure 5a illustrates the surface topography map, showing the typical cloudy and random appearance of webs formed from fiber suspensions. The close-up view (Figure 5b,c) clearly shows a streaky pattern, likely produced by the filter mesh on top of which the CNF dispersion was dewatered to form a film. The distance between the diagonal streaks on the surface is approximately $140 \mu\text{m}$, and the finer regular structure seen on each streak corresponds to the distances between the wires of the dewatering mesh, approximately $48 \mu\text{m}$. The streaky pattern is clearly visible on both sides of the CNF film. 2D spectrum analysis of the photometric stereo based surface topography from an area of several square millimeters confirm the observation made by SEM, which indicated a film with the fibrils randomly oriented in the plane.

The calculated relative permittivity and dielectric loss tangent values for the CNF film obtained from the LCR evaluation are presented as a function of frequency in Figure 6. The deviation span indicate accuracy of the LCR meter for each data point at 100 Hz to 1 MHz. At a 1 kHz frequency the obtained relative permittivity of the CNF film was about 3.47 and the

dielectric loss ($\tan \delta$) about 0.011. The capacitance of the CNF film varied from 78 pF to 73 pF at 100 Hz to 1 MHz, respectively. The average relative permittivity and dielectric losses were 3.38 and 0.071, respectively, measured with SPDR with nominal frequency of 9.97 GHz.

The results for ferroelectric hysteresis are shown in Figure 7. The capacitance or linear component in the polarization data is dominant in the measurements at electric fields from 5 to 15 V/ μm , thus showing that the CNF film has no significant ferroelectric hysteresis at low or moderate electric fields (Figure 7a). However, a nonlinear behavior in polarization is detected at electric fields between 40 to 50 V/ μm (Figure 7b). This suggests that the film has some level of ferroelectric properties at high electric fields. The remanent polarization at 50 V/ μm field is small (0.15 $\mu\text{C}/\text{cm}^2$).

3.2. Piezoelectric sensitivity of CNF films

The operation of four nominally identical CNF sensors with diameter of 15 mm was evaluated with sensitivity measurements (Table 1). The values are presented as mean sensitivity $\pm$ standard deviations for each sensor side. The average sensitivity value for the four CNF sensors was (5.7 $\pm$ 1.2) pC/N.

Thorough sensor characterization was performed for the larger CNF sensor and the PVDF reference sensor. Figure 3b shows the excitation positions for the areal sensitivity distribution measurement. Both sensors had 20 mm diameter electrodes while the shaker's piston was 4 mm in diameter, as illustrated in Figure 3b. Figure 8 shows the CNF and PVDF sensitivity as a

function of the position of the excitation. Negligible variations in sensitivity over the surface were observed. The average sensitivity for the CNF sensor was found to be 4.7 ± 0.9 pC/N, while that of the reference PVDF sensor was 27.5 ± 2.6 pC/N.

The nonlinearity is defined as the maximum deviation of a real transfer function from a linear correlation³⁵. Here the nonlinearity for CNF and PVDF sensors was determined by fitting a first degree polynomial via least-squares minimization (Matlab function polyfit). Figure 9a shows the charge generated by the CNF and PVDF sensors as a function of the dynamic excitation force. The respective fitted polynomials for the sensors are shown as dashed (PVDF $34.01x-9.66$) and solid (CNF $6.51x-1.23$) lines. Instead of the maximum deviation from the linear correlation, the nonlinearity is presented here as the mean $\pm$ standard deviation of data point deviations from the fitted polynomial. The nonlinearity was found to be (0.86 ± 0.48) pC and (6.47 ± 3.76) pC and for CNF and PVDF sensors, respectively.

Figure 9b shows the sensor hysteresis measurements carried out by increasing (solid line and circles) and decreasing (dashed line and crosses) the dynamic excitation force. The maximum difference between the increasing and decreasing measurements was about the same, 0.92 and 0.93 pC for the CNF and PVDF sensors, respectively.

4. Discussion

The SEM images revealed a layered, porous structure, resembling that of an electret material, ElectroMechanical Film (EMFi), widely used in sensor applications^{36,37}. The surface topography of the CNF film is dominated by streaks, approximately 140 μm apart from each other, apparently reproduced from the dewatering fabric mesh¹⁸. Apart from the mesh-induced pattern, the surface of the film is fairly smooth and the fibrous structure is randomly oriented. The density of the CNF film was found to be 1.38 g/cm^3 which is similar to other reports¹⁸. In comparison, the densities of the PVDF²⁹ and EMFi³⁶ sensor materials are 1.78 g/cm^3 and 0.33 g/cm^3 , respectively. Since the CNF film has a porous structure, it is reasonable that CNF film density is slightly lower than that of the PVDF film. On the other hand, the EMFi film has much lower density due to the gas-filled voids separated by polypropylene layers, formed during the manufacturing process.

Relative permittivity of the CNF film was obtained from both LCR and resonator measurements and they match very well, giving a value of about 3.4. Since the measurements were done in ambient conditions, the relative humidity may have caused a small increase in both relative permittivity and dielectric loss, regardless the heat treatment of the films prior to the measurements. However, it is not considered as a significant source of error. The obtained relative permittivity is close to values of dielectric polymers such as polyimide and polytetrafluoroethylene or other organic materials known for their low permittivity³⁸. The change in relative permittivity as a function of frequency was clearly seen from the LCR measurements. At the same time, dielectric losses increased rapidly from 10 kHz onward accompanied with steeper declining of relative permittivity, which is typical indication of a relaxation mechanism taking place (Figure 6). However, the change of relative permittivity was quite small, around 7 %

from 100 Hz to 1 MHz, and it was at similar level as that obtained at ~ 10 GHz, suggesting that only minor level of dielectric relaxation phenomena is occurring due to Maxwell-Wagner-Sillars (MWS) type of the polarization³⁹. Such polarization takes place typically at acoustic frequencies and is associated with e.g. immobilized free charges on the interfaces of different media having contrast in conductivity and permittivity. In the case of EMFi, charges are designedly introduced into the gas-filled voids separated by polypropylene layers while in this case they can be byproduct of the manufacturing process, yet having effectively similar function as in EMFi. Since the sensitivity measurements were carried out at low frequencies, the possible contribution of MWS polarization cannot be excluded at this point. Therefore, the actual mechanism behind the observed behavior remains unclear. However, it can be concluded that utilizing high frequency, the dielectric relaxation expands over a wide frequency spectrum compared to that from MWS relaxation.

In addition, it should be pointed out that the used external electrodes pressed against the surfaces of the sample may cause errors in dielectric and ferroelectric measurements. Any air gaps between the electrodes and the sample film may decrease the coupling of the electric field and measured capacitance. The surface contact makes it difficult to distinguish losses from the materials and the contacts. By using two different dielectric measurements, with and without electrodes, reasonable conclusions could be drawn to address these issues.

The ferroelectric hysteresis measurements showed that the CNF film can withstand quite high electric fields, despite its porous microstructure. Small remanence polarization could be found with electric field above ~ 40 V/ μm and there is an indication that nanocellulose acts like an

incipient organic ferroelectric material under a very high electric field⁴⁰. The high coercive field compared to similar inorganic materials is a commonly known property of organic ferroelectric materials⁴⁰. It should be noted that the above mentioned issue with electrode contacts may influence also to the ferroelectric results. At high electric fields the electrostriction may also contribute to the polarization while ferroelectricity is expected to be dominant effect, which is discussed more later on. However, these results showed that the investigated CNF films need high electric field for poling and exhibit characteristics of ferroelectricity above 40 V/ μm . In such case the observed ferroelectric effect in CNF film results from the permanent dipole moment of CNCs with some level of orientation resulting from the film fabrication process, which is however not apparent from image analyses. Related observations are found in the recent work by Frka-Petecic *et al.* who reported experimental evidence of giant permanent electric-dipole moment in CNCs¹⁴.

The piezoelectric sensors were fabricated from the 45 μm -thick CNF film and copper electrodes evaporated on a PET substrate. The sensitivity of the fabricated sensors was measured using a dedicated measurement setup. All five (four with electrode diameter of 15 mm and one of 20 mm) prepared piezoelectric CNF sensors showed similar sensitivity values, with sensitivity averages from 4.7 to 6.4 pC/N. These results suggest that the nanofibrils are homogeneously distributed inside the film and the sensitivity values are reliable. Both the CNF and the PVDF reference sensors were found to be rather linear within the used measurement range. Linearly proportional force-charge behavior and spontaneous polarization under applied stress, shown in Figure 9, are both characteristic features of piezoelectric materials. Moreover, although the sensor hysteresis in the CNF sensor was small, it was slightly larger than that of the PVDF

sensor which also supports the above mentioned observations. Thus, it can be expected that also hysteresis curve in Figure 7 is ferroelectric in nature.

The sensor structure comprising the CNF films sandwiched between the copper electrodes on PET may affect the measured sensitivity values. The contact between the actual sensing material and the electrode is not as good as in the case of electrodes processed directly on the sensing material. In comparison, less variation in sensitivity values were observed when electrodes were either printed or evaporated directly on PVDF film^{32,33}.

In 2000 Fukada concluded, that a shear piezoelectric coefficient d_{14} for wood is as low as -0.1 pC/N⁴¹, which suggest poor potential for application as piezoelectric material. However, the case is different for cellulose systems at the nanoscale. There are recent experimental evidences indicating that the orientation of CNC crystals has a significant effect on the overall piezoelectric response¹², and that CNC has a permanent dipole momentum¹⁴. It was also suggested that regenerated CNC (cellulose II) has the apparent piezoelectric coefficient on the range 35-60 pC/N¹³. One should point out that the CNF film studied in this work was not optimized as a piezoelectric material and was not polarized nor oriented. However, it cannot be ruled out that the CNF film fabrication method, including filtering and hot-pressing, may have caused some alignment of the cellulose nanofibrils inside the thick film. The sensor sensitivity obtained for the CNF film in this work is expected to significantly increase by direct assembly of the material for optimal alignment of CNC dipoles. The poling procedure, in general, consists of applying an electric field on a processed film for a certain period of time in order to generate piezoelectric properties. The poling (or other type orientation) of the CNF film should lead to the polarization

of the crystalline CNC regions inside the CNF film, further leading to a remarkable increase of piezoelectric effect due to the large piezoelectric coefficient of the crystalline components^{12,14}. In comparison, a sensitivity of about 27.5 pC/N was obtained here for a sensor made from a polarized 28- μ m-thick PVDF film²⁹. This is about four times larger than the sensitivity of the CNF film measured in this work. The initial results of orientation of water-processed CNF-films, using DC voltage, suggest the potential of remarkably higher sensitivity values¹⁶. However, polarization of dry film is difficult due to the entangled and stiff structure of the film and thus, further fabrication process development is required in order to increase the CNF film sensitivity.

5. Conclusion

To conclude, self-standing native cellulose nanofibril (CNF) films were synthesized and their microstructure, and dielectric and piezoelectric properties were studied. Image-based analysis, scanning electron microscopy (SEM), and ferroelectric and electromechanical characterizations were carried out for the CNF films. The obtained results suggest that nanocellulose is a promising new piezoelectric material for sensors, actuators and energy generators, which has obvious applications in fields such as sensors, electronics and biomedical diagnostics.

The authors declare no competing financial interest.

ACKNOWLEDGMENT

The authors acknowledge funding from the Academy of Finland (Dec. No. 137669, 258124, 264743, 267573 and 273663). Author TS appreciatively acknowledge the Riitta ja Jorma J. Takanen, KAUTE, Tauno Tönning and Ulla Tuominen foundations as well as Infotech Oulu Doctoral Program for financial support.
