Social media quote

A dose-response relationship between a shorter length of gestation and out-of-home care placement risk exists. Risk is higher for early and late preterm and early term children in comparison to their full term born peers. Preterm children are also younger at first entry to care.

Facebook: <https://www.facebook.com/suvi.turkka>

Synopsis

Study Question

- The contribution of gestational age to the likelihood of out-of-home care (OHC) placement(s) and, particularly, to the child's age at first entry is unknown. It also remains unclear regarding the extent to which the association amongst gestational age, OHC placement risk and age at first OHC placement is explained by shared common risk factors for both preterm birth and OHC.

What's already known

- Previous studies suggest that preterm birth predisposes to OHC as a form of child protection action.

What this study adds

- OHC placements are more common among preterm and early term children, in comparison to those born full term, and occur at a younger age. Earlier gestational age and higher OHC placement risk may partly reflect the unfavourable pre- and postnatal circumstances that tend to accumulate especially among preterm children.

ABSTRACT

Background: Preterm birth predisposes to child protection action in the form out-of-home care.

Objective: To study the impact of the degree of preterm birth on the likelihood for OHC placement(s) and their timing.

Methods: This population-based register-linkage study assessed the likelihood of OHC placement in different gestational age groups using multivariable Cox regression models. All 193 033 traceable singletons (8324 preterm, 4.3%) live-born in Finland (January 1987 – September 1990), as the first index child of each mother within the cohort period, were followed up until their 18th birthday.

Results: 6562 children (3.4%) experienced OHC. In comparison to full term children (39–41 weeks), those born at 23–33 completed weeks were predisposed to OHC (hazard ratio [HR] 2.11, 95% confidence interval [CI] 1.74, 2.56). For those born late preterm (34–36 weeks) and early term (37–38 weeks), the HRs were 1.54 (95% CI 1.37, 1.73) and 1.19 (95% CI 1.12, 1.26), respectively. Adjustment for parental and child characteristics attenuated the HRs: 23–33 weeks: 1.31 (95% CI 1.07, 1.59), 34–36 weeks 1.17 (95% CI 1.04, 1.31) and 37–38 weeks 1.08 (95% CI 1.02, 1.16). However, the adjusted HRs for first OHC entries at 0–5 years of age were higher: 23–33 weeks 2.29 (95% CI 1.72, 3.05), 34–36 weeks 1.76 (95% CI 1.46, 2.13) and 37–38 weeks 1.40 (95% CI 1.25, 1.56). Among those born preterm or early term, in comparison to their term born peers, no excess risk for OHC was seen after five years.

Conclusions: A dose-response relationship exists between the level of preterm birth and OHC placement risk. OHC placements are more common among early and late preterm, and early term

children, compared with those born full term, and occur at younger age. Perinatal and postnatal adverse circumstances appear to explain the phenomenon only partly.

Keywords

preterm birth; gestational age; cohort studies; child protective services; foster home care; foster children

Word count: 3365

BACKGROUND

Approximately 11% of all live-born infants worldwide are born preterm (at less than 37 completed weeks of gestation).¹ Irrespective of the reason for preterm birth, it may place a long-lasting burden on the childhood family of the preterm child. Families of children born preterm or at very low birthweight (VLBW) (<1500 g) or at extremely low birthweight (ELBW) (<1000 g) appear to have fewer subsequent children, more parenting stress, and poorer parental emotional health, compared with families of term born children.²⁻⁵ Moreover, preterm children appear more likely to experience child protection actions,⁶ such as out-of-home care placements (OHC placement, also known as foster care).⁷⁻⁹ Studies assessing the association of preterm birth and low birthweight on child maltreatment have reported increased risk among preterm and low-birthweight children,¹⁰⁻¹² although contradicting results have also been reported.^{13,14}

Even if the association between preterm birth in general and OHC placements seems fairly well established,⁷⁻⁹ it is unknown whether the higher risk of those who are born preterm is limited to infancy and early childhood or whether it is also present in adolescence, when OHC placements again peak,⁷ and to what extent this higher risk is explained by parental characteristics that predispose to preterm birth and child protection actions. Furthermore, whether this risk varies according to the degree of preterm birth remains unassessed. In this register-linkage study, we were able to assess this by linking population-wide data from administrative registers and to place a special emphasis on common shared risk factors for preterm birth and OHC placement(s). We suggest that preterm birth of a child and the related extra parental burden may vary according to the gestational age of the child, which in turn may be reflected in the OHC entry rates and the timing of first entries.

METHODS

Data sources

The data originated from six national registers, namely: (i) the Medical Birth Register (MBR); (ii) the Central Population Register (CPR); (iii) the Register of Congenital Malformations (RCM); (iv) the Care Register for Health Care (CRHC); (v) the Child Welfare Register (CWR); and (vi) the Census Register. The CWR, maintained by the Finnish Institute for Health and Welfare (THL), and the Census Register, maintained by Statistics Finland are described in Supplementary Material. Other registers and the validity of their data are described in detail elsewhere.²

Cohort members

A total of 235 622 children with a valid personal identity code (99.8% of all live-born children) born in Finland between January 1, 1987 and September 30, 1990 (see Supplementary Material) were first identified from the MBR and served as index children. From this group, we excluded children born from multiple pregnancies (2.2%). Of the 230 308 singleton live-born index children, 3848 (1.7%) were alternatively excluded due to either missing or illogical data on their gestational age or birthweight standard deviation score (SDS). SDS was considered illogical if it was ≤ -6.0 , or, among preterm children, >3.0 . Birthweight standard deviations were calculated using the current national birthweight standards for gestational weeks of 23-43.¹⁵ The Central Population Register enabled the identification of fathers (98.7%) and siblings of the index children who had the same biological mother as the index child. Data on parental socioeconomic position, SEP (updated through December 2014), and data from RCM (January 2015), CRHC (December 2012) and CWR (September 2008) were merged to these data by using encrypted personal identification codes that allow precise individual linkages between registers. Figure 1 describes the cohort. As a total of 33 427 (14.8%) mothers had several index children within the cohort, only the firstborn index

children within the cohort period (n = 193 033) were included in the main analyses to avoid any bias due to repeated data.

Exposure

Gestational age of the index child was the exposure. It was assessed according to the best clinical estimate of the length of gestation at the birth of the index child (ultrasound and/or maternal last menstrual period), and divided into five subgroups: early preterm (23-33 full weeks), late preterm (34- 36 weeks), early term (37-38 weeks), full term (39-41 weeks, reference) and post term (42 weeks). Extremely preterm (23-27 weeks), very preterm (28-31 weeks) and moderately preterm (32-33 weeks) gestational age groups were combined to the early preterm group, in order to ensure a sufficient number of children for the analyses.

Outcomes

First OHC placement prior to the 18th birthday of an index child served as a main outcome. This was assessed using Cox regression model,¹⁶ with age of the index child as the underlying time-scale. Unadjusted and adjusted hazard ratios (HR) with 95% confidence intervals (CI) served as the effect measure.

We hypothesised that the age of a child at first entry to OHC may vary by the gestational age. Therefore, we estimated time-dependent HRs by utilizing the interaction terms calculated separately for five dummy-coded gestational age categories and a three-category time-dependent variable for the follow-up period with cut-off points at 6 and 13 years of age. Baseline time-dependent hazard ratio was calculated for full term children, who served as the reference.

In main analyses the index children were followed up from birth until they were placed into OHC (6562; 3.4%) or until they reached the age of 18 (191 444; 99.2%). Children who emigrated (1009; 0.5%), died (1539; 0.8%) or whose both parents died (223; 0.1%) were censored, according to whichever event took place first. The follow-up period varied from 0 days to 18.0 years and was rounded to the closest 30 days in the analyses, with the median follow-up time being 18.0 years (sum: 3.4 million person years).

Due to the time gap between the births of the cohort (1987 to 1990) and the establishment of the Child Welfare Register in 1991, we ran sensitivity analyses using the follow-up with a starting point at four years of age, as data on OHC placements is not complete for all index children within the cohort prior to that age. An additional sensitivity analysis assessed the sensitivity of the results on the potential unmeasured confounder of the association between the gestational age and the OHC placement (supplemental methods).

In supplemental analyses, conducted in order to validate the results of main analyses, propensity score matching (PSM)^{17,18} served as a tool to balance gestational age groups in terms of background characteristics. Information concerning the utilised PSM method is available in Supplementary Methods. Additionally, the effects of small for gestational age (SGA) status and the maternal socioeconomic position on the OHC placement risk according to gestational age category were assessed (supplemental methods). SGA was defined as infants with birthweight standard deviation score less than -2.

Statistical analysis

Covariates

All Cox regression analyses were stratified according to the birth year of an index child and to the maternal socioeconomic position (SEP) at the time of the child's birth. SEP was categorised as higher officials, lower officials, manual workers, and others. The same categorisation was later used for the paternal SEP. The maternal SEP was set as a covariate to stratify within the model allowing different baseline hazards for each SEP category, rather than adjusting for it, as it violated the Cox assumption for proportional hazards when used as a standard covariate; the tests based on the Schoenfeld residuals showed significant non-proportionality for the SEP categories.

Six models were fitted by adding variables in clusters. These models included (1) maternal age and marital status at the birth of the index child; (2) smoking in pregnancy and late onset of antenatal care; (3) the number of previous live-born children (biological and adoptive), the length of previous interbirth interval and urban residence; (4) the first maternal in-hospital treatment period for a psychiatric disorder as a time-dependent covariate; (5) child's sex, SGA, developmental disorder and/or intellectual disability, cerebral palsy and major birth anomaly; (6) paternal SEP and age at the child's birth. Supplementary methods (eFigures 1 and 2; eTable 1) present detailed information on the covariates. The decision to exclude parental deaths, a known risk factor for OHC,⁷ from the models is shown in eTable 2 and eFigure 2.

SPSS 24 served as main statistical software (IBM Corp, Armonk, NY, USA). Additionally, in subanalyses, the IBM SPSS PS Matching plugin was utilised in propensity score matching. To examine the proportional hazard assumption, we employed R software (R Foundation for

Statistical Computing, Vienna, Austria) version 3.50 with statistical code R packages ‘survival’ and ‘survminer’ to compute proportional hazard tests and visualise the Schoenfeld residuals.

Missing data

Among the 193 012 women, the numbers of missing observations by covariate were as follows: 972 (0.5%) for maternal marital status, 3812 (2.0%) for smoking in pregnancy, 1573 (0.8%) for the late onset of antenatal care, 1 (0.0%) for the mode of delivery, and 1838 (1.0%) for maternal SEP. Of the fathers 2233 (1.2%) had no data on the SEP. A total of 95.4% of cases were complete. As the proportions of missing values in each of the variables was small (2.0% or less), and the sample size was large, we applied single imputation with most likely values (no data on smoking in pregnancy - did not smoke; no data on the late onset of antenatal care – did not participate late to antenatal care; no data on maternal marital status – was unmarried, no data on SEP – SEP category ‘Other’). The variable on the mode of delivery was not included in the models. In sensitivity analysis mother and child dyads with missing data were excluded.

Ethics approval

The study was approved by applicable register authorities and the ethical approval for the study was granted by the local Ethics committees.

RESULTS

Characteristics of the index children

Table 1 and eTable 3 describe the characteristics of the index children and their parents per gestational age groups of the children. A total of 41 315 (21.4%) of the 193 033 index children were born before 39 full weeks of gestation: 4.3% were preterm and 17.1% early term. Of all index

children, 6562 (3.4%) experienced OHC; preterm children were placed into OHC at a younger age than their full term born peers (Figure 2, eFigure 3). Developmental and intellectual disabilities, cerebral palsies, smallness for gestational age and major birth anomalies appeared more frequently among children born before 39 weeks of gestation, and especially among those born early preterm. A total of 1.4% of children did not have information on fatherhood registered to the CPR, among the preterm index children this percentage was 3.8.

Characteristics of the parents

Of the mothers, 2.0% had their first psychiatric in-hospital treatment period between Jan 1st, 1969 and the birth of the index child and 6.0% before the end of the follow-up. Of those mothers whose child was born preterm, 3.1% had been hospitalized due to psychiatric disorder prior to the birth of the child, and 8.3% before the end of the follow-up. Corresponding percentages for mothers of full-term children were 1.9% and 5.7%. Among the preterm index children mothers were more likely to be under 20 years or over 35 years of age at the birth of the child. Teenage parents were more common with a lower gestational age of the child, as were the parents with a lower SEP. Unmarried mothers and mothers initiating their prenatal visits later than at 22nd weeks of gestation were also overrepresented among the preterm and early term children. Similarly, smoking in pregnancy and short interbirth intervals preceding the index child appeared to be more common among mothers of preterm or early term children.

Gestational age and later placement to Out-of-Home Care

There was no difference in the association between the gestational age and OHC placements between boys and girls (P for interaction $> .9$), therefore we report the results pooled for both sexes.

Preterm index children had a higher overall risk for OHC placement, in comparison to their full term born peers (Figure 3a, eTable 4). The results of the final adjusted Cox regression analyses indicated that an adjustment for covariates, whose univariate associations for OHC placement are presented in eTable 5, had a considerable combined effect on gestational age groups impact on the OHC placement risk. They could not, however, completely explain the differences between the gestational age categories. Further analyses utilising the time-dependent variable for the follow-up period with cut-off points at 6 and 13 years of age revealed that the higher overall risk for OHC placement of those born preterm was explained by the preterm born children's increased risk for placement at the 0 to 5 years of age (Figure 3b, eTable 6).

Sensitivity analyses

The CWR provides complete data on OHC placements after January 1, 1991, but regarding placements before it, only those first placements that were followed by an OHC placement period after January 1, 1991 are available. As the partially incomplete OHC data during infancy and early childhood (see Supplementary Material) may affect the results, we ran the analyses by setting the onset of follow-up to four years of age. The overall risk of those born preterm or early term attenuated when compared with the main analysis (eTable 7). However, the specific risk for placement prior to six years of age remained (eTable 8).

We performed a sensitivity analysis to assess possible residual confounding, and found that potential for unmeasured confounders may exist. However, such confounding would require a relatively large association with both exposure and out-of-home placement (supplementary methods). Additionally, the results of the main analysis excluding mother and child dyads with missing data demonstrated similar point estimates (supplementary methods).

The results of a subanalysis, in which we ignored any intra-mother correlation by including all 226 439 mother-child pairs, were consistent with the results of the main analyses, indicating increasing HRs in relation to declining gestational age (eTables 9 and 10).

Propensity Score Matching

The results based on propensity score matched data confirm those of the main analyses (eTables 11 and 12, eFigure 4). The matched analyses indicated that an improved covariate balance across different gestational age categories may have resulted in a higher estimated OHC placement risk among preterm children.

COMMENT

Principal findings

In our nationwide cohort study of 193 033 children, we assessed out-of-home care (OHC) placement(s) and the timing of the first OHC entries in preterm and early term born children. We placed particular weight on the effect of early, mainly mother-related, adverse circumstances. We found that preterm birth is not only associated with an increased risk for out-of-home care placement(s) but also that the more preterm the child is the higher the risk is. It is worthy to note that a moderately increased risk for OHC is also present in the large group of early term children. The higher risk for those born prior to 39 weeks' gestation is explained by the increased number of OHC placements before the age of six. The higher risk is only partly associated with maternal SEP at the birth of the index child and is mainly associated with a range of other adverse family characteristics that, however, explain only a part of the phenomenon.

Strengths of the study

The main strength of the present study is the coverage of the nationwide data: it comprises all singleton live births within a 3.8-year period in Finland. The linkage of several population-wide registries provided longitudinal individual level data with minimal loss to follow-up. Time-dependent Cox regression analyses allowed us to examine the changes in probabilities over time periods and the variation in follow-up time. As the Finnish population is ethnically homogeneous and only 0.8% of the Finnish population had an immigrant background in 1990,¹⁹ the potential disparities in OHC placement risks among index children due to ethnic variation are likely to be small.

Limitations of the data

Due to the time gap between the births of the cohort and establishment of the Child Welfare Register, information on placements among children who were placed into OHC before January 1, 1991, but never after that, was not available. The magnitude of the bias can be considered as moderate and to lead to underestimation of OHC placements at early childhood. Therefore, if we had complete data from January 1, 1987, then the disparities within gestational age categories and between the different models might have been more like the results of those analyses of our study, which utilises four years of age as the onset of the follow-up period. Unfortunately, the reasons for OHC placements are not recorded in the CWR. Furthermore, we lacked information about whether the estimation of the gestational age of the index child was based on maternal last menstrual period (LMP) or on foetal ultrasound. A previous study reported that 60% of the newborns in northern Finland had a gestational age estimate based on LMP during the 1985 to 1986,²⁰ and, as gestational age estimation based on LMP increases the estimated length of

gestation,²¹ the rates of preterm births may have indeed decreased as a consequence. The effect of this on our results may, however, be considered as marginal.

Interpretation

This study does not entirely explain relationship between preterm birth and higher OHC placement risk. In addition to extra parental burden, other mechanisms could be contributing to the association between preterm birth and increased OHC placement risk especially at 0 to 5 years of age, as compared with full term born children: OHC entries of small children tend to associate with early adverse parental characteristics,^{6,22,23} which appeared to be accumulated among preterm children within our study, and explained part of the association. Furthermore, impaired parental–child bonding due to preterm birth could lead to increased rates of first OHC placements at an early age, at least among early preterm children. Current literature, however, does not universally support this explanation.²⁴ Additionally, it may be possible that the evident association is, in part, explained by unrecognised factors or by the fact that the information on the gestational age of a child is not blinded from those who decide on the out-of-home care placement.

Few previous studies have assessed the effect of preterm birth on OHC placement risk and none of them take into account the level of preterm birth or the age at first placement. A population-based study of all children born in Western Australia between 1990 and 2010 assessed preterm born children as one group. This study indicated a nearly 1.6-fold risk (HR 1.56, 95% CI 1.43, 1.70) for OHC placement, in comparison with children born at 37th week of gestation or later, after adjustment for the sex, ethnicity, disability and birthweight for the gestational age of the child as well as for parental SEP, age and mental health or substance related admissions.⁸ Similarly, a Finnish study indicated a 1.4- to 1.5-fold risk for OHC placement among preterm-born children,

again as one group, according to unadjusted separate models for girls (HR 1.36, 95% CI 1.05, 1.78) and boys (HR 1.47, 95% CI 1.15, 1.89).⁷ One study that, instead of OHC placements, assessed the risk for child protection registration among nearly 160 000 children in West Sussex, found that the shorter the gestational age was the higher the risk of child protection registration was, even after adjustment for maternal age and socioeconomic position.⁶ The study also showed linear trends across birthweight z-score groups, indicating that rates of registrations increased by declining foetal growth. Comparability of study results between countries, however, can be affected by the differences in the organisation of child protection services.

Conclusion

This population-based study shows a dose-response relationship between the shorter length of gestation and out-of-home care (OHC) placement risk: early preterm, late preterm and even early term children are at a higher risk in comparison to their full term born peers. The higher risk is explained by an increased number of OHC placements before the age of six. The study results further indicate that the association between gestational age and placement risk is only partly explained by shared common risk factors for both preterm birth and OHC placement, underlining the role of preterm birth as a potential risk factor for childhood adversity regardless of parental SEP or other early circumstances. This highlights the importance of directing professionals working with preterm children to increased sensitivity in noticing need of help and support. The consequences of preterm or early term births are not only medical but also social and affect both the child and the entire family.

Conflict of Interest

The authors report no relevant potential conflicts of interest to disclose.

Funding

The study is supported by the Academy of Finland (Skidi-Kids program for 2010-2013 and grants 127437, 129306, 130326, 134791, 263924, 274794 and 315690 to Dr. Kajantie, and Clinical Researcher Grant 288966 to Dr. Hovi); European Commission (Horizon2020 award 733280 RECAP Research on Children and Adults Born Preterm to Dr Kajantie); the Doctoral Programs of public Health, University of Helsinki (to Dr. Alenius); the Finnish Foundation for Pediatric Research (to Drs. SD – Standard deviation; OHC - out-of-home care; CPR - Central Population Register

^a Severe infant morbidity includes neonatal diagnoses: seizure, intraventricular haemorrhage (IVH), cerebral infarction, periventricular leukomalacia, birth trauma, hypoxic ischemic encephalopathy (HIE), necrotizing enterocolitis (NEC), septicaemia, pneumonia, primary atelectasis, patent ductus arteriosus (PDA), infant respiratory distress syndrome (IRDS) and respiratory failure of the newborn. Composition of this covariate is presented in detail elsewhere.²

^b Maternal marital status at the birth of the index child.

^c *Pregnancy disorder* includes gestational diabetes, gestational hypertensive disorder, and intrahepatic cholestasis of pregnancy. A complete list of diagnoses included in this covariate is available in Supplementary Methods.

^d 1st appointment to the antenatal clinic after 22 completed weeks of gestation.

^e Biological or adoptive.

^f Maternal in-hospital treatment(s) for alcohol and/or substance abuse at the birth or prior to the birth of the index child. Composition of this covariate is presented in detail in eTable 1.

^g Maternal in-hospital treatment(s) for any psychiatric disorder at the birth or prior to the birth of the index child. A complete list of diagnoses included in this covariate is available in Supplementary Methods.

^h Maternal in-hospital treatment(s) for any psychiatric disorder from the establishment of The Care Register for Health Care (1967) to the end of follow-up. A complete list of diagnoses included in this covariate is available in Supplementary Methods.

ⁱ *Other* includes entrepreneurs, farmers, students, pensioners, unemployed, housewives and mothers or fathers with unclassifiable or unknown SEP.

The amount of missing data were 0.5% for maternal marital status, 2.0% for maternal smoking in pregnancy, 0.8% for the onset of antenatal care, 0.0% (n = 1) for the mode of delivery, and 1.0% for maternal SEP. For paternal SEP the amount of missing data was 1.2%. Data on other variables presented in this table are complete. Note that 47.0% of mothers did not have previous child, and 42.6% of mothers did not have a subsequent one.

FIGURE LEGENDS

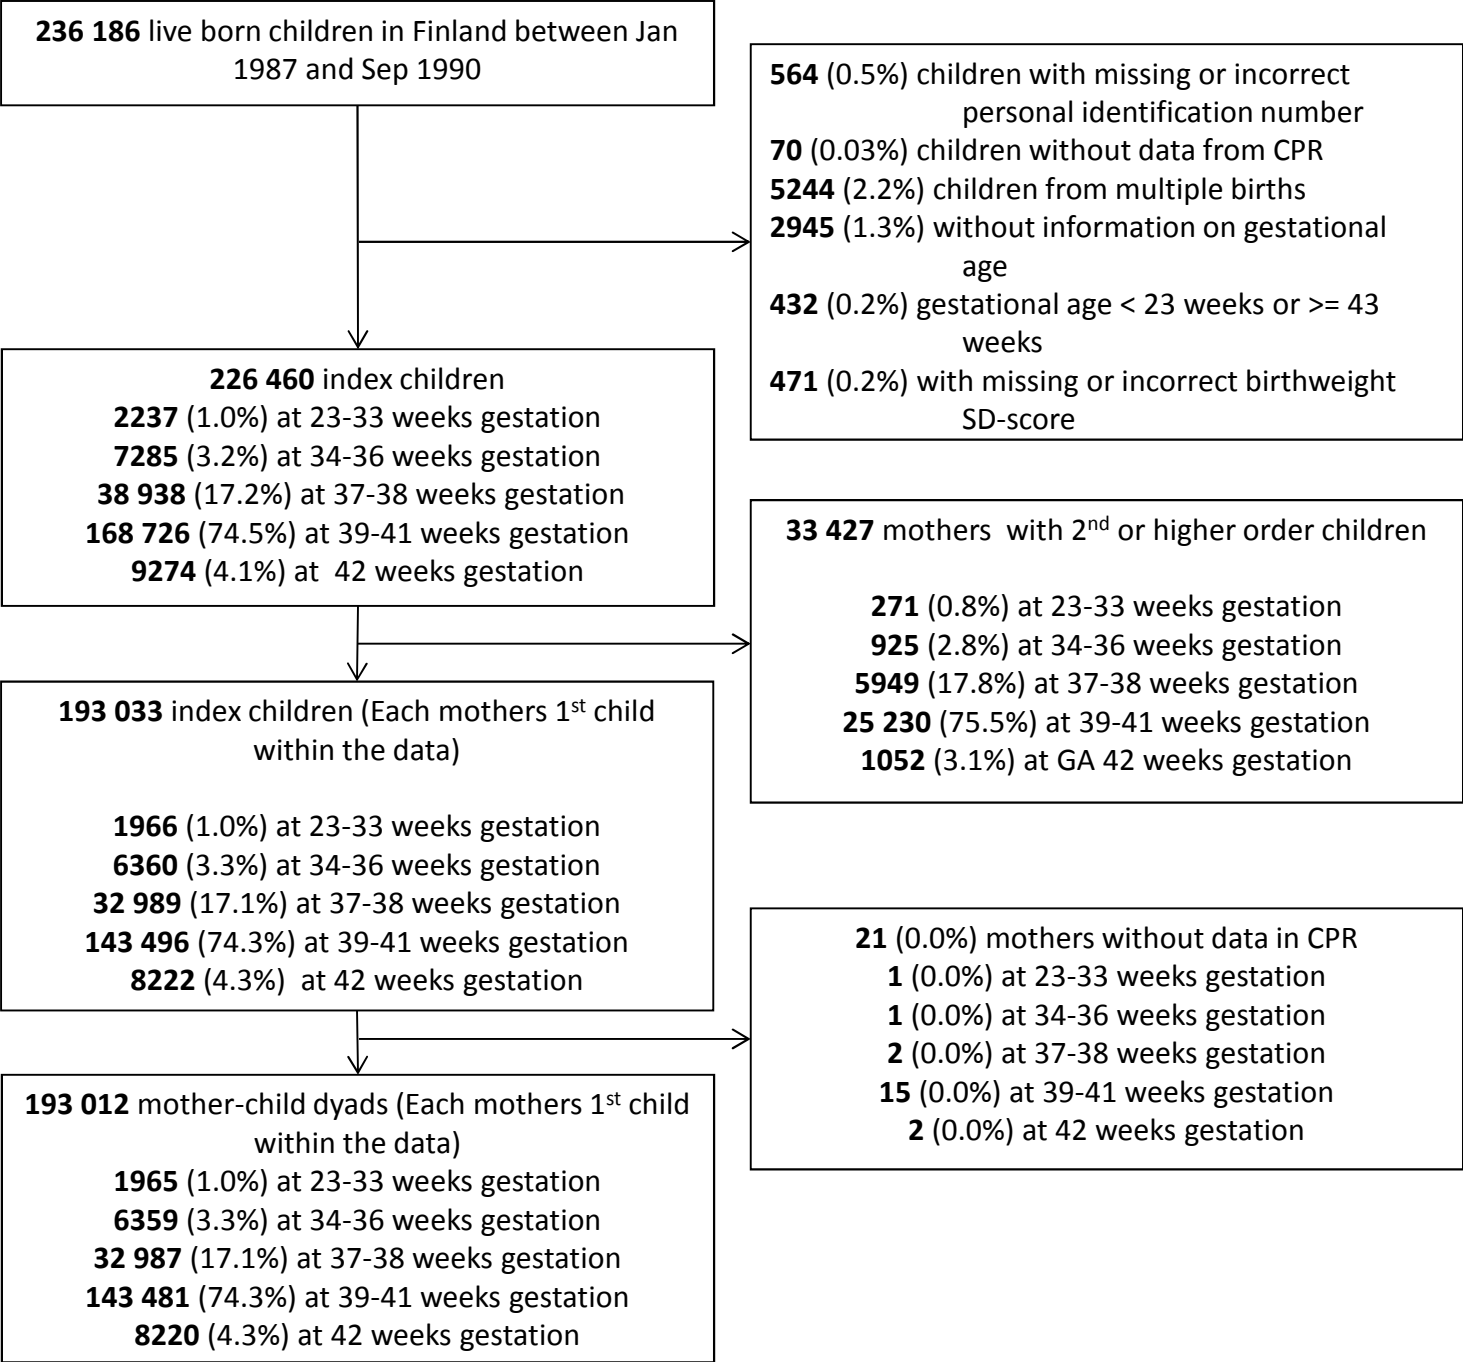

Figure 1. Flow-chart.

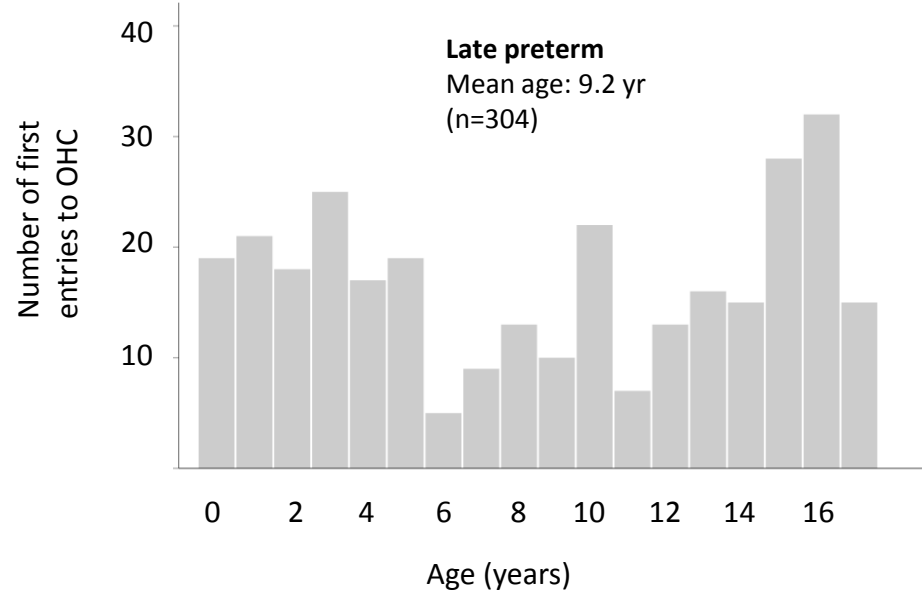

Figure 2. The number of first out-of-home care (OHC) entries by the age (years) of the index child within different gestational age categories. The Figure covers only the first index child of each mother within the cohort (a total of 6 562 first entries, of which 328 were those of born post term).

Figure 3. Hazard ratios (HR; 95% confidence intervals) for OHC placement by the gestational age category of the first index child of each mother (gestational age 39-41 completed weeks is the reference [HR = 1.0]).

Figure 3. [Footnotes]:

- A. Follow-up period from 0 to 18 years of age. Model 0 is the unadjusted model. Model 0s is stratified by the maternal socioeconomic position at the birth of the index child, and the birth year of the index child. Model 6 is stratified as Model 0s and adjusted for the maternal age and marital status at the birth of the index child, maternal smoking in pregnancy, late onset of antenatal care, the number of previous maternal live-born children, previous maternal interbirth interval, urban residence of the mother at the birth of the index child, time-dependent covariate for the onset of the first maternal psychiatric in-hospital treatment period, smallness for gestational age status, developmental disorder or intellectual disability, cerebral palsy, major anomaly, the sex of the index child, the paternal socioeconomic position and age at the birth of the index child. Models from 1 to 5 are available in eTable 4.
- B. Follow-up periods of 0– 5 years; 6–12 years; 13–17 years. Fully adjusted hazard ratios (95% confidence intervals) for OHC placement within certain age categories. Analyses are stratified and adjusted as in Model 6 at Figure 3A. Model 0s is presented in eTable 6.

Out-of-Home Care Placements of Children and Adolescents Born Preterm: A Register-Based Cohort Study

Alenius et al. 2019

Supplementary Material

SUPPLEMENTARY METHODS

Description of the registers

The Child Welfare Register (CWR) provides complete data on children's out-of-home care (OHC) entries, durations and placement settings since January 1, 1991. It also encompasses retroactive data for those children who were recorded to CWR both before *and* after its actual establishment in 1991. Hence, CWR lacks data on such children who were returned home from OHC placement prior to the establishment of the CWR, and who were never again placed into OHC after that time point. The Finnish Institute for Health and Welfare THL (STAKES until December 31, 2008) compiles and processes the CWR data. The data are regarded to be reliable. The comparability of the data during the follow-up period (until September 30, 2008) is good, as no changes appear in the concepts and definitions until 2007, when reporting of the type of care settings, primarily, was slightly modified.¹ The CWR does not provide data on the causes of OHC placements because of the difficulties associated with the categorisation and collection of such data nor does it provide information on any involvement of child protection authorities beyond OHC placements. In 1987, according to the National Research and Developmental Centre for Welfare and Health (STAKES) survey² the main reason for the placement of a child into the family- or institutional care were harmful environmental factors (86.0%) such as alcohol and substance abuse of the parents, neglect of care and parental mental problems. The developmental and behavioural factors of the child were the reason for placement in 8.9% of cases and social problems in 5.1% of cases. The information on whether the distributions of the reasons for placement to family- or institutional care differ between preterm born children and the general population is not available in these statistics.

In addition to the CWR data on those born between 1987 and 1990, we were able to access additional complete aggregated data from the CWR for years 1991 to 2008, which allowed us to estimate the proportion of children who enter OHC in the first four years of life but who do not return into the OHC placement during subsequent years, and were therefore missed in our setting. The percentage of missed OHC placements for children placed into OHC prior to six months of age was 12.0%. Corresponding percentages for children who were one, two, or three years of age at first

entry to OHC were: 11.6%, 6.2%, and 4.1%. This translates to a loss of approximately 86 OHC placements due to the time gap between the births within the cohort and the establishment of the CWR.

The Registers at Statistics Finland encompass population-wide individual-level data on education, employment and socioeconomic position (SEP) of all citizens in Finland. The classification of SEP within this study is based on the Statistics Finland's classification standard of socioeconomic groups from 1983 and 1989.^{3,4} These classifications take into account a person's occupation, occupational status, the nature or type of the work and main activity (such as being a family member, student, pensioner, unemployed or a part of the labour force).

Cohort members

Live born children with valid personal identity code in Finland between January 1, 1987 and September 30, 1990, identified from MBR, formed the initial study population. This time period was chosen because the MBR is available from January 1, 1987 onwards, and substantial changes occurred in the MBR on October 1, 1990, and would have affected the uniformity of the data in use.

Additional information on covariates included in the models

We did not adjust for maternal or paternal SEP *after* the birth of the index child in order to avoid reverse causality. Instead, we used maternal and paternal socioeconomic positions at the time of the birth of the index child, and categorised them in four subgroups: SEP Group I included upper officials, SEP group II included lower officials, SEP Group III included manual workers, and the SEP Group IV, 'Others', included all other groups (such as students, pensioners, farmers, entrepreneurs, unemployed and parents with an unclassifiable or unknown SEP). For index children born before the July 1, 1988, we used information on parental SEP registered December 31, 1985, and for the rest of the index children, the SEP registered by December 31, 1990. Information on parental SEP between 1986 and 1989 was unavailable due to SEP data documentation that, at that time, occurred at an interval of five years only.

Maternal and paternal ages at the birth of the index child were categorised in three groups: less than 20 years, from 20 to 34 years, and 35 years or older. The MBR served as a source for maternal marital status (married or unmarried) at the birth of the child and for information on maternal smoking in pregnancy (yes/no). Data on smoking were recorded to the MBR as it was reported at the first antenatal clinic appointment, usually at 9 to 10 completed weeks of gestation. As MBR also encompasses the date of the first maternal visit to the antenatal clinic, we assessed this data by formulating a variable to reflect maternal in-time attendance to antenatal care (*first appointment before the end of the 22nd gestational week/ first appointment in 23rd week of gestation or later*). In Finland, pregnant women must visit a doctor or a maternity and child welfare clinic for a health check before the fifth month of pregnancy in order to be able to claim a maternity grant; namely a maternity package (including baby clothes, care products and other materials) or a tax-free monetary benefit. It is rare not to claim for that, and not to attend antenatal care in a timely fashion; only 1.3% of mothers within the cohort did not attend antenatal care before the end of their 22nd week of gestation (**Table 1, eTable 3**). Data on maternal pregnancy disorders were derived from the MBR and the Finnish Care Register for Health Care (CRHC). A maternal pregnancy disorder was

defined as present if any of the following three diagnoses appeared within the MBR or CRHC during the index pregnancy (from 20 weeks before the expected date of delivery of the index child to 90 days after the actual birth date): (1) gestational diabetes (*International Classification of Diseases, Eighth Revision* code 761.10, *International Classification of Diseases, Ninth Revision* codes 6480A and 6488A), (2) maternal hypertensive disorder (*International Classification of Diseases, Eighth Revision* codes 637.01 and 637.036-37.99 or (*International Classification of Diseases, Ninth Revision* codes 6420X-6429C) and (3) intrahepatic cholestasis of pregnancy (*International Classification of Diseases, Eighth Revision* codes 639.00-639.09 or (*International Classification of Diseases, Ninth Revision* codes 6467A and 6467X). Information on the number of maternal previous live born children (biological or adoptive) came from the CPR, and was categorized as *none*, *one* or *two or more*. Accordingly, as closely spaced pregnancies may reflect cumulative stressors, and the burden of daily caretaking of the children due to insufficient parental resources, we assessed the time interval between the births of the index child and the child's previous sibling, that is, the previous maternal interbirth interval (*more than 18 months or no previous siblings/ 18 months or less*).⁵ The dates of the births of the siblings of the index children were also available from the CPR. Information on maternal place of residence at the birth of the index child came from the MBR and was categorised as *urban* or *nonurban*.

Maternal psychiatric disorders^{6,7} and alcohol and drug abuse or addictions^{5,8,9} serve as strong risk factors for out-of-home care placement and child maltreatment; thus we in our main analyses adjusted for in-hospital treated psychiatric disorder in time-dependent manner (*no first maternal in-hospital psychiatric treatment periods during follow up/ maternal first in-hospital psychiatric treatment period within one year/ maternal first in-hospital psychiatric treatment period over one year ago*). This cut-off point in the time-dependent variable was selected because the risk for OHC-placement appeared to be highest during the first year following the onset of the first maternal psychiatric treatment period (**eFigure 1**). Diagnoses included in this time-dependent covariate cover dementias, non-organic psychiatric disorders and alcohol intoxication if alcohol intoxication diagnosis was set as the main diagnosis (*International Classification of Diseases, Tenth Revision (ICD-10)*: all codes in categories F00 to F03, F11 to F19, G30, the diagnosis F05.1, and corresponding diagnosis codes that follow *International Classification of Diseases, Ninth Revision (ICD-9)*: all codes in categories 290 to 292, 295 to 309, 312 to 319 and codes 2941A, 3050A, 3310A and 4378A, as well as corresponding diagnosis codes that follow *International Classification of Diseases, Eighth Revision (ICD-8)*: all codes in categories 290 to 291, 295 to 301, 302.10 to 308, and codes 310 and 294.40). Any first maternal in-hospital treatment period was defined as having at least one of the above mentioned diagnoses for the first time within the Finnish Care Register for Health Care (CRHC) between the year 1969 (the start of ICD-8 classification) and the end of the follow-up period. All above mentioned diagnosis codes were included, regardless of the subspecialty of the in-hospital care period. The variable on maternal alcohol and substance abuse (**eTable 1**) was not included in the models as a separate covariate as 53.5% of those mothers who had any psychiatric disorder had also in-hospital treatment period resulting from alcohol and substance abuse.

As disabling conditions, such as developmental and intellectual disabilities of the child, may affect the propensity for out-of-home care placement(s), other child protection services, or for child

maltreatment,¹⁰⁻¹² we made an aggregate variable reflecting this condition. The variable comprises of (1) any developmental disorders (*International Classification of Diseases, Tenth Revision*: all diagnosis codes in category F84; and *International Classification of Diseases, Ninth Revision*: codes 2990, 2998 and 2999) and (2) any intellectual disabilities (*International Classification of Diseases, Tenth Revision*: all diagnosis codes in categories F70 to F79; and *International Classification of Diseases, Ninth Revision*: diagnosis codes in categories 317 to 319). A developmental and/or intellectual disability of the index child was defined to as having at least one of the diagnoses above documented within the Finnish Care Register for Health Care during the follow-up period.

Even though most of the parents cope well regardless of the added challenges of daily caretaking of a child with a disability we considered cerebral palsy (CP) as a such characteristic of a child that could serve as a risk factor for OHC placement.¹³ Therefore, we incorporated a variable reflecting this condition in our analyses. An index child was defined to have cerebral palsy if any of the diagnosis codes in category G80 (*International Classification of Diseases, Tenth Revision*) or in category 343 (*International Classification of Diseases, Ninth Revision*) appeared in the Finnish Care Register for Health Care during the follow-up period. Variables reflecting developmental and/or intellectual disabilities and cerebral palsy were included in the models as two separate covariates as 13.4% of index children with a developmental disorder and/or intellectual disability also had cerebral palsy.

The birth weight standard deviation scores were assessed by using current national growth charts.¹⁴ The index child's smallness for gestational age status (SGA) was defined as less than -2 SD as recommended in a consensus statement of the International Societies of Pediatric Endocrinology and Growth Hormone Research Society.¹⁵ Data on major congenital anomalies originated from RCM and was dichotomised (*any major anomaly/ no major anomalies*).

Information on parental dates of death came from PCR. As maternal deaths were more frequent among the mothers' of preterm born infants and serve as a rational risk factor for outcome, we tested the time-dependent effect of maternal death on the out-of-home care placement risk. After adding this time-dependent variable (*mother alive/ mother died within one year/ mother died over one year ago*) the estimates of different gestational age groups remained virtually unchanged. After adjusting for the time-dependent variable of paternal death (*father alive/ father dead*), the biggest difference in estimates was among the early preterm group, in which the HR attenuated from 1.98 (95% CI 1.63, 2.40) to 1.84 (95% CI 1.50, 2.26) (**eTable 2**). As parental deaths were rare during the follow-up period of our study (**Table 1, eTable 3**) and because we considered their effect as marginal on the outcome, we decided not to adjust for it. Justification for selected time cut-off points in time-dependent variables of maternal and parental deaths is presented in **eFigure 2ab**.

Propensity score matching

In sensitivity analyses propensity score matching (PSM) was applied to match cases (*gestational age 23 to 38 weeks, or 42 completed weeks of gestation*) with controls (*gestational age 39 to 41 completed weeks of gestation*) who shared a similar value of propensity score.¹⁶ As the aim of propensity score matching was to investigate the effect of balanced covariate distributions among groups with different gestational ages, variables the propensity score was estimated with were the

same as incorporated in Models (0s to 6) in main and sensitivity analyses with one exception: a maternal in-hospital treated psychiatric disorder *prior* to the birth of the index child served as a covariate that was incorporated in matching algorithm instead of the time-dependent one described above. Diagnosis codes included in this conventional covariate of maternal psychiatric disorder prior to the birth of the index child were: all codes in categories 290 to 292, 295 to 309, 312 to 319 and codes 2941A, 3050A, 3310A and 4378A (*International Classification of Diseases, Ninth Revision*); and the corresponding diagnosis codes that follow *International Classification of Diseases, Eighth Revision*: all codes from categories 290 to 291, 295 to 301 and 310, as well as codes from 302.10 to 308 and code 294.40). Thus the propensity score was estimated with the following variables: (1) the maternal socioeconomic position (SEP) at the birth of the index child, (2) the birth year of the index child, (3) the maternal age at the birth of the index child, (4) the maternal marital status at the birth of the index child, (5) maternal smoking in pregnancy, (6) late onset of antenatal care, (7) the number of previous maternal live born children, (8) previous maternal interbirth interval, (9) the urban location of birth of the index child, (10) any maternal psychiatric disorder *prior* to the birth of the index child, (11) smallness for gestational age (SGA) status of the index child, (12) developmental disorder or intellectual disability of the child, (13) cerebral palsy, (14) major anomaly, (15) sex of the index child, (16) the paternal socioeconomic position, and (17) the paternal age at the birth of the index child. These covariates were chosen based on previous literature^{6,8,17,18} or on empirical knowledge. They were recoded as two to five category covariates, even if they were continuous in main analyses. The data were divided in five smaller data according to maternal SEP (including separate category for missing data), and a one-to-one nearest neighbour matching without replacement was utilised within each of these data with a maximum 0.01 difference in propensity scores eligible for use in matching. These data were then rejoined for analysis. A total of 178 (0.3%) cases were excluded due to failure to satisfy a matching criterion. Standardised mean differences of the propensity scores and the covariates served as tools for the assessment of the balance between the matched groups.

Assessment of unmeasured confounding

E-value¹⁹ was employed as a tool to assess the effect of potential unmeasured confounding. It illustrates the magnitude of unmeasured confounding that is “needed” to negate the observed results. In the fully adjusted model in the main analyses the E-value for the early preterm group was 1.95 indicating that residual confounding could explain the observed association if there is an unmeasured covariate with a relative risk association at least of magnitude 1.95 with both preterm birth and out-of-home care placement prior to the age of 18 years. The E-values for late preterm and early term groups were 1.62 and 1.37. (The corresponding lower limits of the confidence intervals were 1.34, 1.27, and 1.21.) In light of the observed effects of the covariates in the models it is not inconceivable that such residual confounding exists that could annul the observed results at least among those born at 34 completed weeks of gestation or later.

Assessment of missing data by exclusion of cases with incomplete data

In main analyses we included index children with missing data in our analyses, by coding the missing values within dichotomous categorical covariates as 0, and by coding the missing data on socioeconomic position (SEP) into category 'Other'. In sensitivity analysis we excluded cases with incomplete data. The results of this sensitivity analysis showed a minimal change on point estimates: the largest difference in fully adjusted estimates was among the early preterm group, where the HR attenuated from 1.31 (95% CI 1.07, 1.59) to 1.28 (95% CI 1.03, 1.59). The estimates of the late preterm group attenuated from HR 1.17 (95% CI 1.04, 1.31) to HR 1.16 (95% CI 1.03, 1.32), and those of the early term group from HR 1.08 (95% CI 1.02, 1.16) to HR 1.07 (95% CI 1.00, 1.16).

Effect of Smallness for Gestational Age (SGA) on out-of-home care placement risk

The effect of smallness for gestational age (SGA) status differed by gestational age category (P for interaction $< .001$). For full term born children who were born small for gestational age the hazard ratio for out-of-home care placement was HR 2.82 (95% CI 2.50, 3.18). The corresponding hazard ratios for early term, late preterm and early preterm groups were HR 2.81 (95% CI 2.37, 3.34), HR 1.50 (95% CI 1.10, 2.04) and HR 0.78 (95% CI 0.45, 1.36). The effect of smallness for gestational age (SGA) status on placement risk declined with decreasing gestational age so that smallness for gestational age had no effect within the early preterm group.

Effect of maternal socioeconomic position on out-of-home care placement risk

The effect of maternal socioeconomic position at the birth of the index child on the placement risk of the child differed significantly in the five gestational categories (P for interaction .022) with a slight increase in late preterm group. The hazard ratios for early preterm, late preterm, early term and full term groups were HR 4.02 (95% CI 2.59, 6.24), HR 4.71 (95% CI 3.64, 6.10), HR 3.58 (95% CI 3.19, 4.01) and HR 3.34 (95% CI 3.15, 3.54).

SUPPLEMENTARY FIGURES:

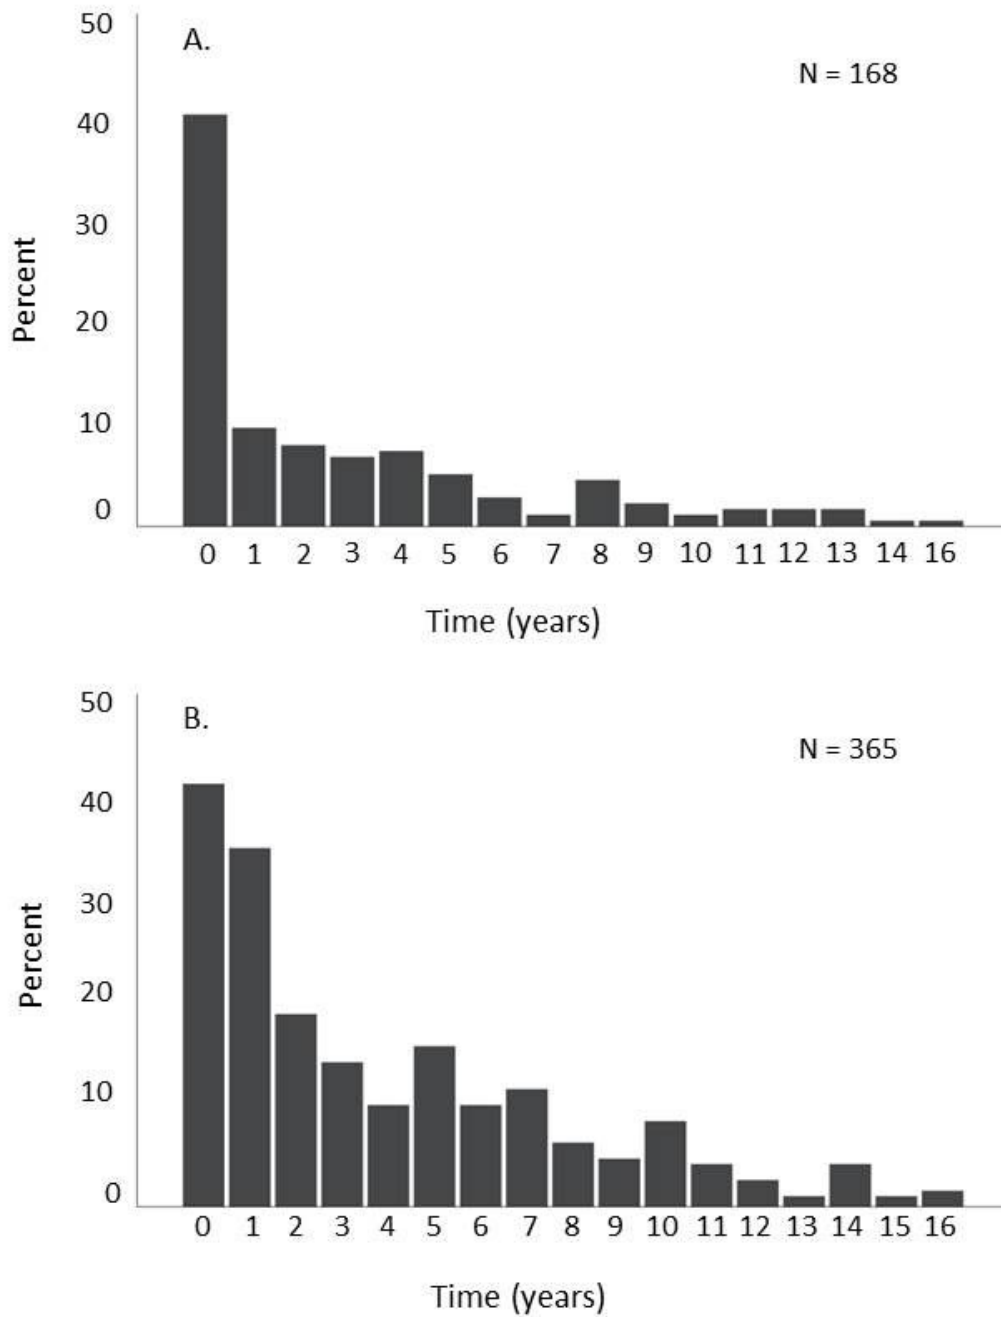

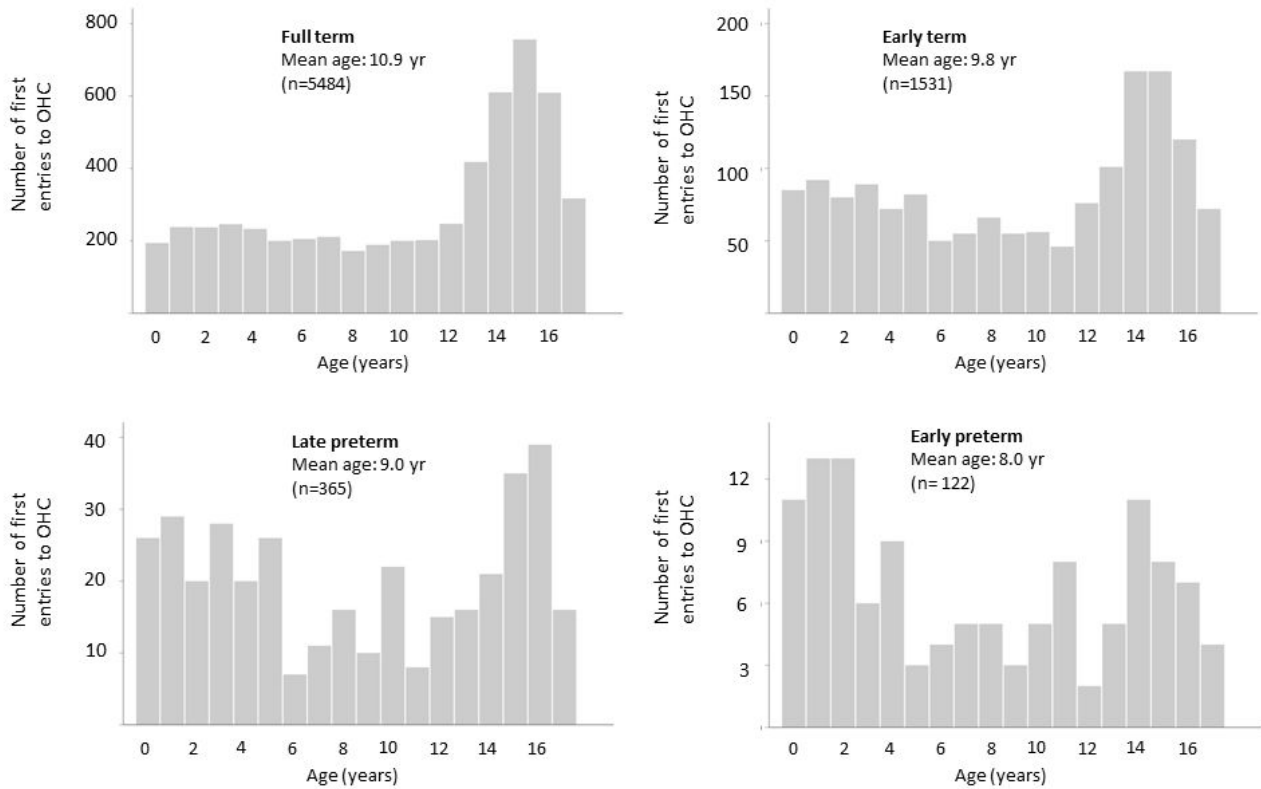

Figure 1. The time (years) elapsed from the onset of the first maternal psychiatric in-hospital treatment period after the birth of the index child to the index child's first out-of-home care (OHC) entry. Figure covers only the first child of each mother within the cohort.

eFigure 2ab. Time (complete years) from maternal (A.) or paternal (B.) death to the onset of the first out-of-home care (OHC) placement of the index child within all gestational age categories combined. Note that none of the index children were placed into OHC 15 or 17 years after the death of the mother, or 17 years after the death of the father. Figure includes only the first child of each mother within the study.

eFigure 3. The number of first entries to out-of-home care (OHC) by the age (years) of the index child within different gestational age categories. Figure covers all index children within the cohort (a total of 7870 first entries, of which 368 were those of born post term).

eFigure 4. Comparisons of the results of the main analyses (original data) and the results of the analyses using propensity score matched (PSM) data. Only the first child of each mother within the cohort is included. Figure A illustrates the overall hazard ratios (95% confidence intervals) for out-of-home care (OHC) placement(s) and figure B presents hazard ratios (95% confidence intervals) for OHC placement at certain age categories (0–5 years of age; 6–12 years of age; 13–17 years of age) of the index child at first entry.

OHC - out-of-home care; CPR - Central Population Register

^a Severe infant morbidity includes neonatal diagnoses: seizure, IVH, cerebral infarction, periventricular leukomalacia, birth trauma, HIE, NEC, sepsis/septicemia, pneumonia, primary atelectasis, PDA, IRDS, and respiratory failure of the newborn. Composition of this covariate is presented in detail elsewhere.²⁰

^b Maternal marital status at the birth of the index child.

^c *Pregnancy disorder* includes gestational diabetes, gestational hypertensive disorder and intrahepatic cholestasis of pregnancy. A complete list of diagnoses included in this variable is available in Supplementary Methods.

^d First appointment to the antenatal clinic after 22 completed weeks of gestation.

^e Biological or adoptive.

^f In-hospital treatment(s) for alcohol and/or substance abuse at the birth or prior to the birth of the index child. Composition of this covariate is presented in detail in the eTable 1.

^g In-hospital treatment(s) for any psychiatric disorder at the birth or prior to the birth of the index child. A complete list of diagnoses included in this covariate is available in the Supplementary Methods.

^h Maternal in-hospital treatment(s) for any psychiatric disorder in the time between the establishment of The Care Register for Health Care (1967) and the end of follow-up. A complete list of diagnoses included in this covariate is available in the Supplementary Methods.

ⁱ *Other* includes entrepreneurs, farmers, students, pensioners, unemployed, housewives and mothers or fathers with unclassifiable or unknown SEP.

The amount of missing data were 0.5% for maternal marital status, 1.9% for maternal smoking in pregnancy, 0.8% for the onset of antenatal care, 0.0% ($n = 1$) for the mode of delivery, and 0.8% for maternal SEP. For paternal SEP the amount of missing data were 1.1%. Data on other variables presented in this table are complete. Note that 40.1% of mothers did not have a previous child, and 43.2% of mothers did not have a subsequent one.

eTable 4. The hazard ratios (HR) (95% confidence intervals (CI)) for out-of-home care (OHC) placement by the gestational age^a of the index child. *The follow-up period begins at the birth of the index child. Only the first child of each mother^b (N = 193 012) within the cohort is included.*

^a Completed weeks' gestation.

^b Mothers without data from the Central Population Register (CPR); 21 (0.0%).

Model 0: Unadjusted model.

Model 0s: Unadjusted model, stratified by the year of birth of the index child and by the maternal socioeconomic position at the birth of the index child.

Model 1: Model 0s + adjusted for the maternal age and marital status at the birth of the index child.

Model 2: Model 1 + adjusted for maternal smoking in pregnancy and late onset of antenatal care

Model 3: Model 2 + adjusted for the number of previous maternal live born children, previous maternal interbirth interval and for the urban location of the birth of the index child.

Model 4: Model 3 + adjusted for the time-dependent variable of any maternal psychiatric disorder.

Model 5: Model 4 + adjusted for the smallness for gestational age status (SGA), developmental disorder or intellectual disability, cerebral palsy, major anomaly and the sex of the index child.

Model 6: Model 5 + adjusted for the paternal socioeconomic position and age at the birth of index child

eTable 5. Univariate association (hazard ratios (HR) and 95% confidence intervals (CIs)) between the individual covariates and likelihood for out-of-home care (OHC) placement.

Independent effect of covariates	HR (95% CI)
The year of birth of the Index child (<i>1987 versus 1988 or 1989 or 1990</i>)	
	<i>1988</i> 1.05 (0.98, 1.18)
	<i>1989</i> 1.15 (1.08, 1.22)
	<i>1990</i> 1.23 (1.15, 1.31)
Index child's sex (<i>boy vs girl</i>)	1.04 (0.99, 1.08)
Small for gestational age; SGA (<i>yes</i>)	2.72 (2.49, 2.98)
Developmental disorder and/or Intellectual disability; (<i>yes</i>)	4.33 (3.73, 5.04)
Severe infant morbidity (<i>yes</i>) ^a	1.26 (1.03, 1.56)
Cerebral palsy (<i>yes</i>)	2.46 (1.88, 3.24)
One or more major anomalies (<i>yes</i>)	2.69 (2.35, 3.08)
Urban location of birth (<i>yes</i>)	1.90 (1.81, 1.99)
Maternal age at index child's birth	0.92 (0.92, 0.93)
Maternal age at index child's birth (<i>20 to 34 years vs 19 years or less or 35 years or more</i>)	
	<i>19 years or less</i> 4.21 (3.92, 4.53)
	<i>35 years or more</i> 0.91 (0.85, 0.98)
Information on fatherhood not registered to the Central Population Register (<i>yes</i>)	5.53 (5.02, 6.09)
Maternal marital status at index child's birth (<i>unmarried vs married</i>)	3.60 (3.44, 3.76)
Smoking during pregnancy (<i>yes</i>)	4.73 (4.52, 4.94)
Pregnancy disorder (<i>yes</i>) ^b	0.95 (0.88, 1.02)
Late onset of antenatal care (<i>yes</i>)	3.21 (2.92, 3.53)
Mode of delivery (<i>spontaneous vaginal vs instrumental or cesarean section</i>)	
	<i>Instrumental</i> 0.78 (0.68, 0.89)
	<i>Cesarean section</i> 1.03 (0.97, 1.10)
The number of previous maternal children (<i>none vs one or two or more</i>)	
	<i>One</i> 0.86 (0.82, 0.91)
	<i>Two or more</i> 1.11 (1.05, 1.17)
Previous interbirth interval length < 18 months (<i>yes</i>)	1.71 (1.58, 1.85)
Subsequent interbirth interval length > 18 months (<i>yes</i>)	1.46 (1.35, 1.59)
Maternal alcohol and/or substance abuse (<i>yes</i>) ^c	8.75 (8.06, 9.51)
Maternal any psychiatric disorder (<i>yes</i>) ^d	8.21 (7.68, 8.77)
Maternal socioeconomic position (<i>lower official vs higher official or manual worker or other</i>)	
	<i>Higher official</i> 0.41 (0.36, 0.46)
	<i>Manual worker</i> 2.28 (2.15, 2.43)
	<i>Other</i> 3.39 (3.20, 3.59)
Paternal age at index child's birth	0.97 (0.97, 0.98)
Paternal age at index child's birth (<i>20 to 34 years vs. 19 years or less or 35 years or more</i>)	
	<i>19 years or less</i> 5.01 (4.39, 5.72)
	<i>35 years or more</i> 1.40 (1.30, 1.51)
Paternal Socioeconomic position (<i>lower official vs. higher official or manual worker or other</i>)	
	<i>Higher official</i> 0.42 (0.37, 0.47)
	<i>Manual worker</i> 2.31 (2.17, 2.45)
	<i>Other</i> 3.30 (3.11, 3.50)

^a Severe infant morbidity includes neonatal diagnoses: seizure, IVH, cerebral infarction, periventricular leukomalacia, birth trauma, HIE, NEC, sepsis/septicaemia, pneumonia, primary atelectasis, PDA, IRDS and respiratory failure of the newborn. Composition of this covariate is presented in detail elsewhere.²⁰

^b Pregnancy disorder includes gestational diabetes, gestational hypertensive disorders and intrahepatic cholestasis of pregnancy (ICP). Composition of this covariate is presented in detail in Supplementary Methods.

^c Maternal in-hospital treated alcohol and/or substance abuse prior to or at the birth of the index child. Diagnoses and diagnose codes included in this covariate are available in eTable 1.

^d Maternal in-hospital treatment(s) for any psychiatric disorder prior to or at the birth of the index child. A complete list of diagnoses included in this variable is available in the Supplementary Methods.

BPD - bronchopulmonary dysplasia; ICH - intrahepatic cholestasis of pregnancy; IRDS - infant respiratory distress syndrome; IVH - intraventricular hemorrhage; HIE - hypoxic ischemic encephalopathy; NEC - necrotizing enterocolitis; PDA - patent ductus arteriosus

eTable 6. The hazard ratios (HR) (95% confidence intervals (CI)) for out-of-home care (OHC) placement by the gestational age^a of the index child and by the age category of the index child at first OHC entry. *The follow-up period begins at the birth of the index child. Only the first child of each mother^b (N = 193 012) within the cohort is included.*

Model 0: Unadjusted model.

Model 0s: Unadjusted model, stratified by the year of birth of the index child and by the maternal socioeconomic position at the birth of the index child.

Model 1: Model 0s + adjusted for the maternal age and marital status at the birth of the index child.

Model 2: Model 1 + adjusted for maternal smoking in pregnancy and late onset of antenatal care.

Model 3: Model 2 + adjusted for the number of previous maternal live born children, previous maternal interbirth interval and for the urban location of the birth of the index child.

Model 4: Model 3 + adjusted for time-dependent variable of any maternal psychiatric disorder.

Model 5: Model 4 + adjusted for the smallness for gestational age (SGA) status, developmental disorder or intellectual disability, cerebral palsy, major anomaly and the sex of the index child.

Model 6: Model 5 + adjusted for the paternal socioeconomic position and age at the birth of index child.

eTable 10.
